Secure routing in multi-hop wireless networks

ad hoc network routing protocols;

attacks on routing;

secured ad hoc network routing protocols;

Outline

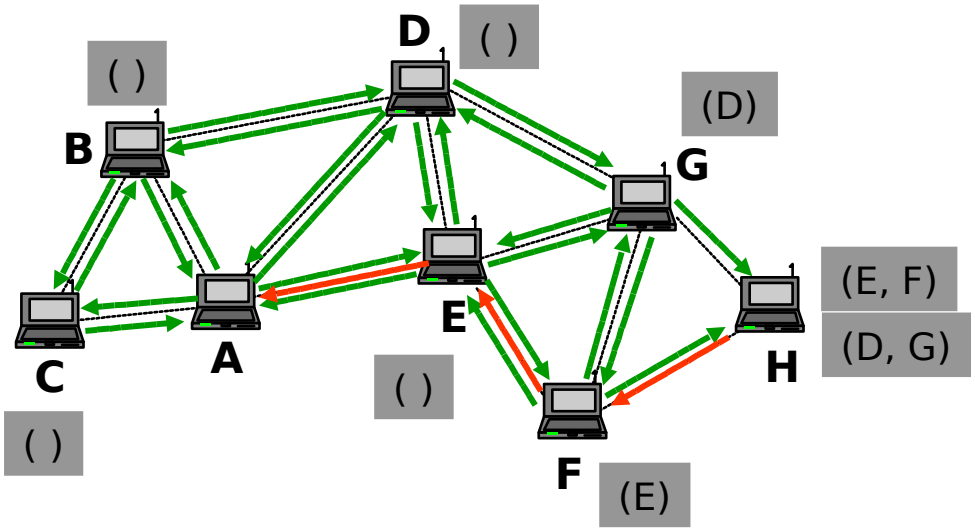
Ad hoc network routing protocols

- topology-based protocols
  - proactive
    - distance vector based (e.g., DSDV)
    - link-state (e.g., OLSR)
  - reactive (on-demand)
    - distance vector based (e.g., AODV)
    - source routing (e.g., DSR)
- position-based protocols
    - greedy forwarding (e.g., GPSR, GOAFR)
    - restricted directional flooding (e.g., DREAM, LAR)
- hybrid approaches

Example: Dynamic Source Routing (DSR)

- on-demand source routing protocol
- two components:
  - route discovery
    - used only when source S attempts to send a packet to destination D
    - based on flooding of Route Requests (RREQ) and returning Route Replies (RREP)
  - route maintenance
    - makes S able to detect route errors (e.g., if a link along that route no longer works)

DSR Route Discovery illustrated



Source: A; Destination: H

A → *: [RREQ, id, A, H; ()]
B → *: [RREQ, id, A, H; (B)]
C → *: [RREQ, id, A, H; (C)]
D → *: [RREQ, id, A, H; (D)]
E → *: [RREQ, id, A, H; (E)]
F → *: [RREQ, id, A, H; (E, F)]
G → *: [RREQ, id, A, H; (D,G)]

H → A: [RREP, <source route>; (E, F)]

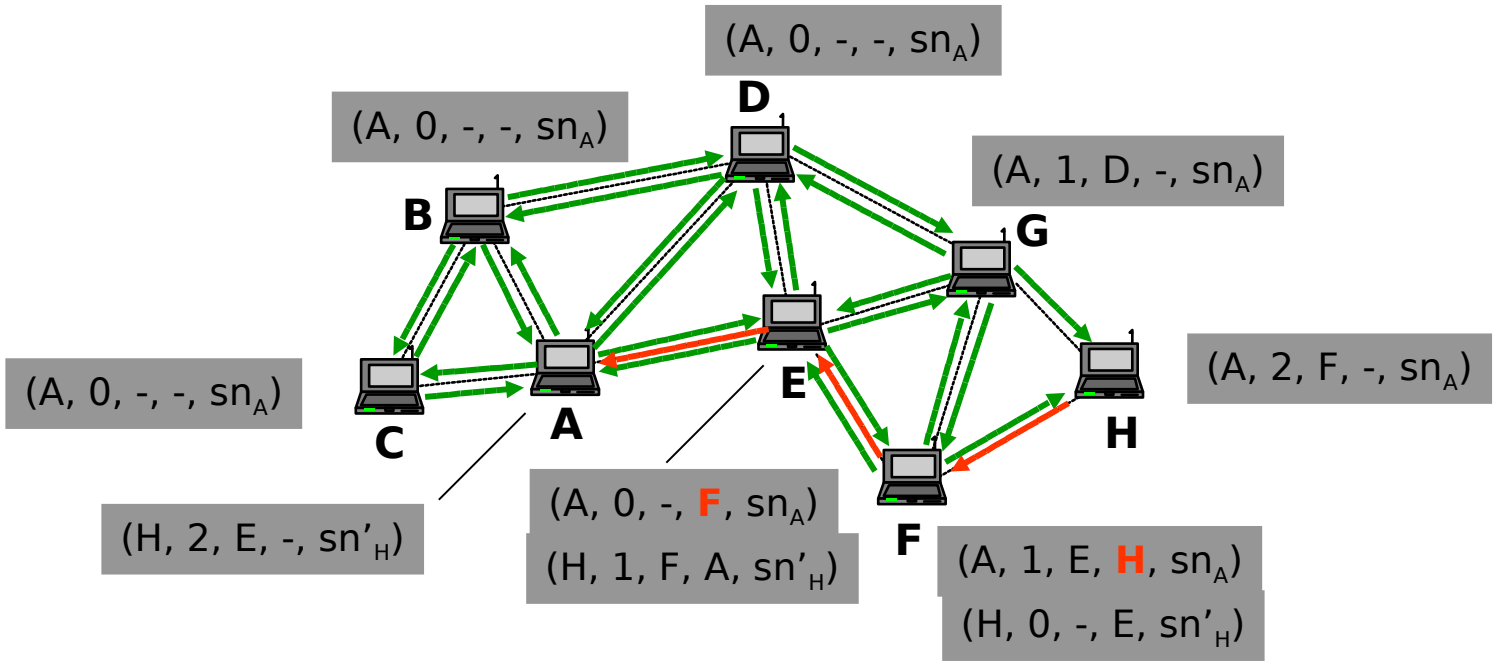
where <source route> is obtained

- from the route cache of H
- by reversing the route received in the RREQ
  - works only if all the links along the discovered route are bidirectional
  - IEEE 802.11 assumes that links are bidirectional
- by executing a route discovery from H to A
  - discovered route from A to H is piggy backed to avoid infinite recursion

Example: Ad-hoc On-demand Distance Vector routing (AODV)

- on-demand distance vector routing
- operation is similar to that of DSR but the nodes maintain routing tables instead of route caches
- a routing table entry contains the following:
  - destination identifier
  - number of hops needed to reach the destination
  - identifier of the next hop towards the destination
  - list of precursor nodes (that may forward packets to the destination via this node)
  - destination sequence number (which helps to ensure loop-freedom and to detect out-of-date routing information)

AODV Route Discovery illustrated



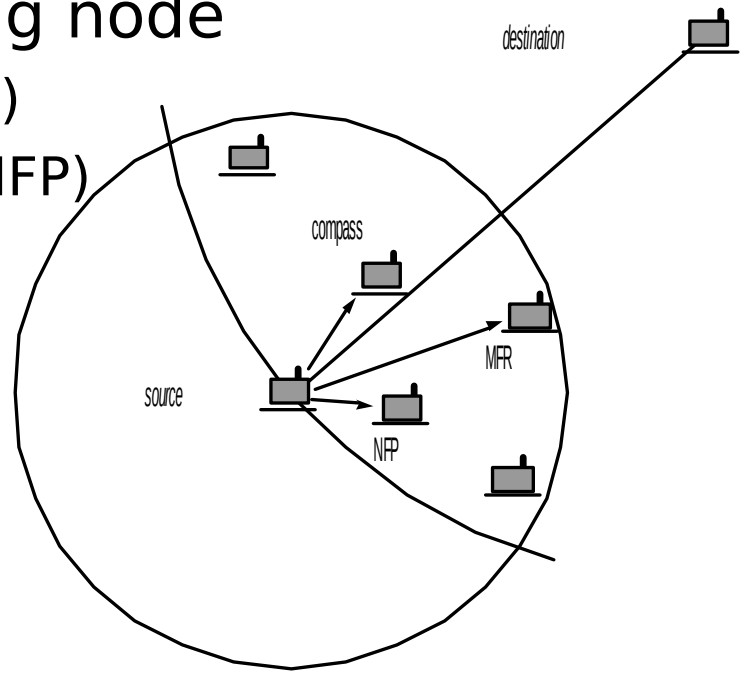
A → *: [RREQ, id, A, H, 0, sn_A, sn_H]
B → *: [RREQ, id, A, H, 1, sn_A, sn_H]
C → *: [RREQ, id, A, H, 1, sn_A, sn_H]
D → *: [RREQ, id, A, H, 1, sn_A, sn_H]
E → *: [RREQ, id, A, H, 1, sn_A, sn_H]
F → *: [RREQ, id, A, H, 2, sn_A, sn_H]
G → *: [RREQ, id, A, H, 2, sn_A, sn_H]

H → F: [RREP, A, H, 0, sn'_H]
F → E: [RREP, A, H, 1, sn'_H]
E → A: [RREP, A, H, 2, sn'_H]

Example: Position-based greedy forwarding

- assumptions
  - nodes are aware of their own positions and that of their neighbors
  - packet header contains the position of the destination

- packet is forwarded to a neighbor that is closer to the destination than the forwarding node
  - Most Forward within Radius (MFR)
  - Nearest with Forward Progress (NFP)
  - Compass forwarding
  - Random forwarding



- additional mechanisms are needed to cope with local minimums (dead-ends)

Chapter outline

Attacks on routing protocols (1/2)

- general objectives of attacks
  - increase adversarial control over the communications between some nodes;
  - degrade the quality of the service provided by the network;
  - increase the resource consumption of some nodes (e.g., CPU, memory, or energy).

- adversary model
  - insider adversary
    - can corrupt legitimate nodes
  - the attacker is not all-powerful
    - it is not physically present everywhere
    - it launches attacks from regular devices

Attacks on routing protocols (2/2)

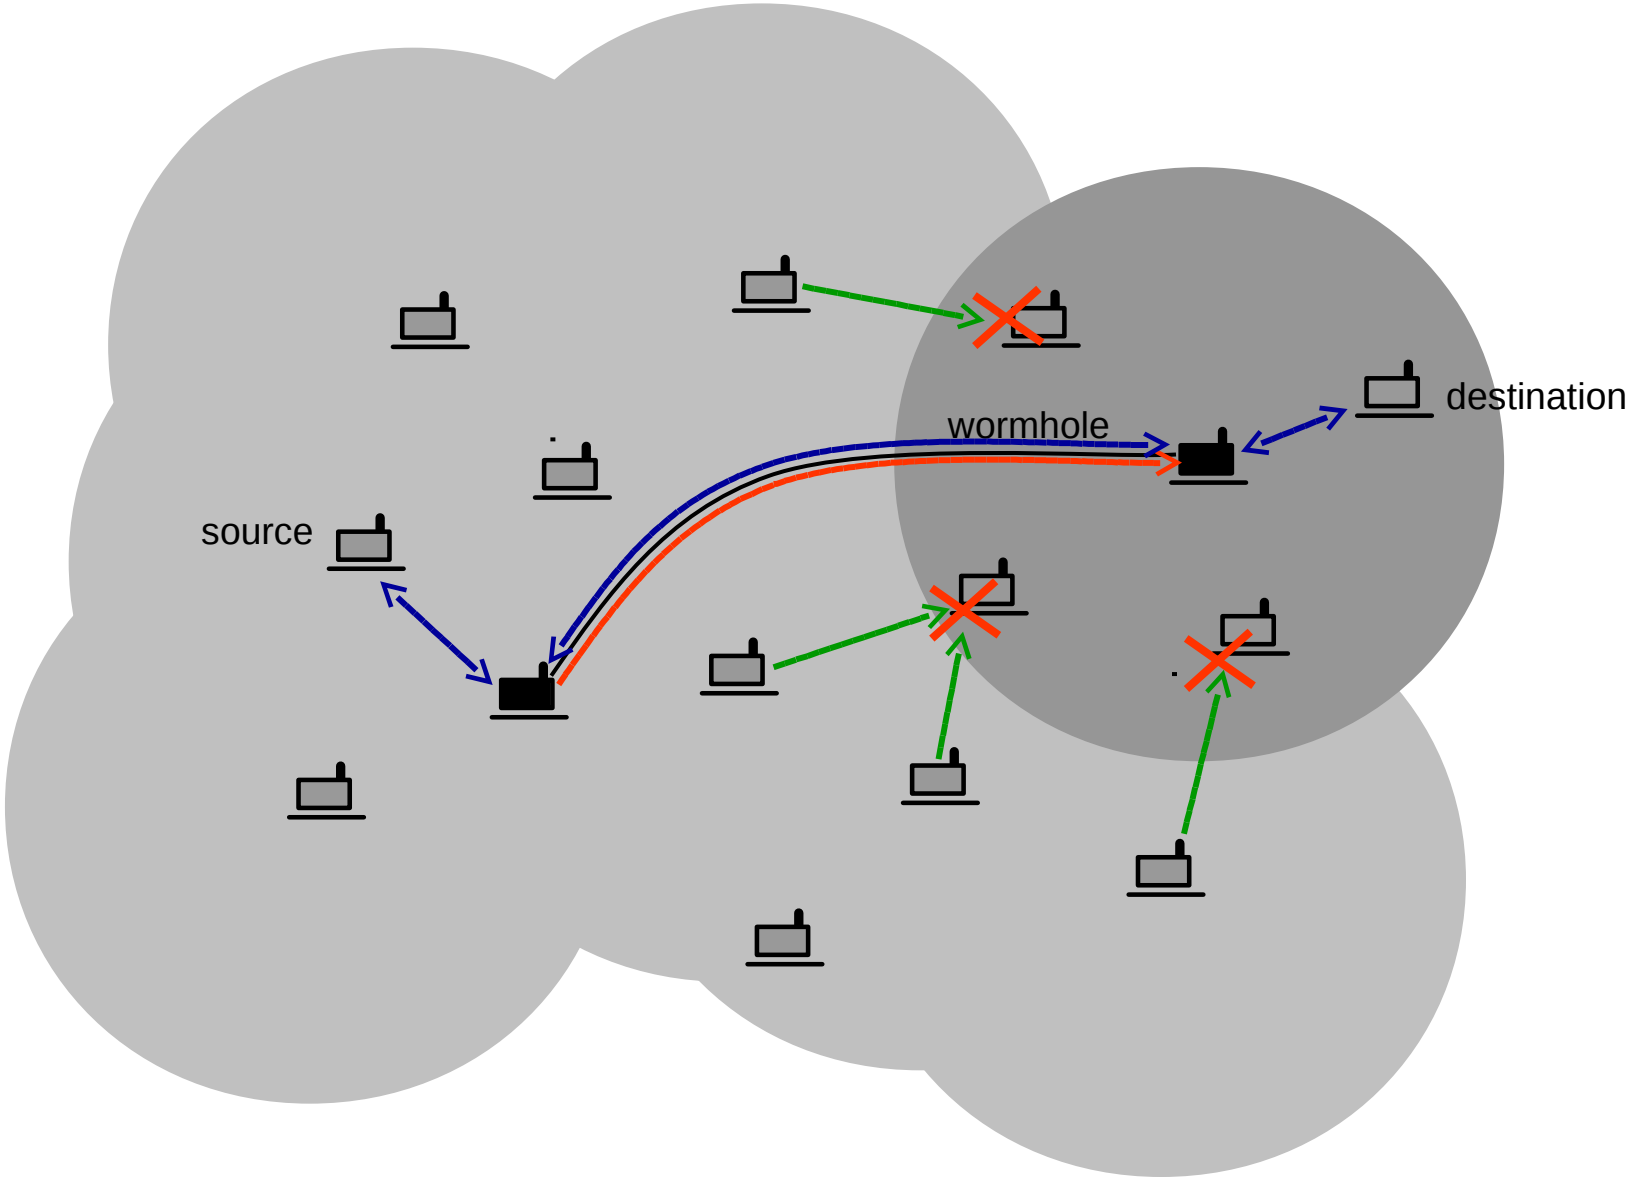
- attack mechanisms
  - eavesdropping, replaying, modifying, and deleting control packets
  - fabricating control packets containing fake routing information (forgery)
  - fabricating control packets under a fake identity (spoofing)
  - dropping data packets (attack against the forwarding function)
  - wormholes and tunneling

- types of attacks
  - route disruption
  - route diversion
  - creation of incorrect routing state
  - generation of extra control traffic
  - creation of a gray hole

Route disruption

- the adversary prevents a route from being discovered between two nodes that are otherwise connected
- the primary objective of this attack is to degrade the quality of service provided by the network
  - the two victims cannot communicate, and
  - other nodes can also suffer and be coerced to use suboptimal routes
- attack mechanisms that can be used to mount this attack:
  - dropping route request or route reply messages on a vertex cut
  - forging route error messages
  - combining wormhole/tunneling and control packet dropping

Example: Route disruption in DSR with wormhole



Route diversion

- due to the presence of the adversary, the protocol establishes routes that are different from those that it would establish, if the adversary did not interfere with the execution of the protocol

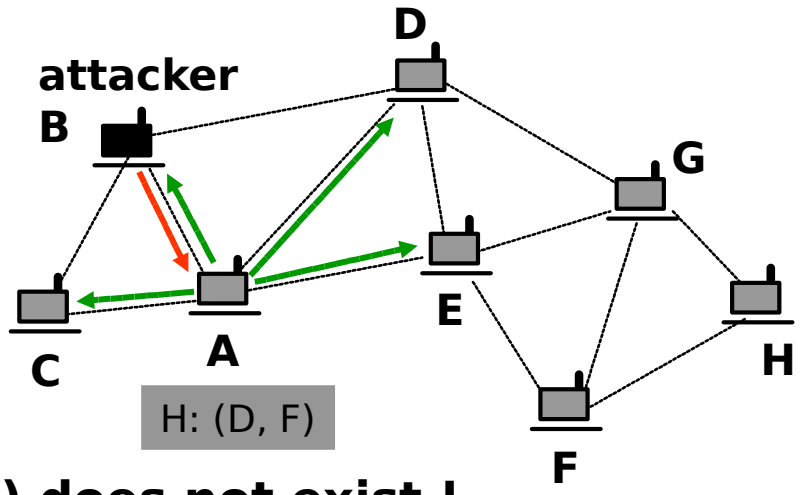
- the objective of route diversion can be
  - to increase adversarial control over the communications between some victim nodes
    - the adversary tries to achieve that the diverted routes contain one of the nodes that it controls or a link that it can observe
    - the adversary can eavesdrop or modify data sent between the victim nodes easier
  - to increase the resource consumption of some nodes
    - many routes are diverted towards a victim that becomes overloaded
  - degrade quality of service
    - by increasing the length of the discovered routes, and thereby, increasing the end-to-end delay between some nodes

- route diversion can be achieved by
  - forging or manipulating routing control messages
  - dropping routing control messages
  - setting up a wormhole/tunnel

Creation of incorrect routing state

- this attack aims at jeopardizing the routing state in some nodes so that the state appears to be correct but, in fact, it is not
  - data packets routed using that state will never reach their destinations
- the objective of creating incorrect routing state is
  - to increase the resource consumption of some nodes
    - the victims will use their incorrect state to forward data packets, until they learn that something goes wrong
  - to degrade the quality of service
- can be achieved by
  - spoofing, forging, modifying, or dropping control packets

Example: Creation of incorrect routing state in DSR



Route (A, D, F, H) does not exist !

A → *: [RREQ, id, A, H; ()]
B → A: [RREP, <src route>, A, H; (D, F)]

Generation of extra control traffic

- injecting spoofed control packets into the network
- aiming at increasing resource consumption due to the fact that such control packets are often flooded in the entire network

Setting up a gray hole

- an adversarial node selectively drops data packets that it should forward

- the objective is
  - to degrade the quality of service
    - packet delivery ratio between some nodes can decrease considerably
  - to increase resource consumption
    - wasting the resources of those nodes that forward the data packets that are finally dropped by the adversary

- implementation is trivial
  - adversarial node participates in the route establishment
  - when it receives data packets for forwarding, it drops them
  - even better if combined with wormhole/tunneling

Chapter outline

Countermeasures

- authentication of control packets
  - using MACs or digital signatures
- protection of mutable information in control packets
  - using MACs or digital signatures
  - often complemented with the use of one-way hash functions
- detecting wormholes and tunnels
- combating gray holes
  - using multi-path routing
  - using a “detect and react” approach

Authentication of control packets

- To defend against spoofing
  - ***control packets should be authenticated by their originators***

- To prevent the creation of an incorrect routing state
  - ***authenticity should be verifiable by the target of the control packet***
  - ***each node that updates its routing state as a result of processing the control packet must be able to verify its authenticity***
  - ***each node that processes and re-broadcasts or forwards the control packet must be able to verify its authenticity***

- as it is not known in advance which nodes will process a given control packet, we need a ***broadcast authentication*** scheme

Protection of mutable information in control packets

- often, intermediate nodes add information to the control packet before re-broadcasting or forwarding it (hop count, node list, etc.)
- this added information is not protected by control packet origin authentication
- ***each node that adds information to the packet should authenticate that information in such a way that each node that acts upon that information can verify its authenticity***
- this works for traceable additions (e.g., adding node identifiers), but what about untraceable additions (e.g., increasing the hop count)?

Protection of traceable modifications

- the entire control packet can be re-signed by each node that modifies it

- problems:
  - signatures can be removed from the end
    - one-way hash chains can be used (e.g., Ariadne)
    - efficient aggregate signatures provide better solution
  - re-signing increases the resource consumption of the nodes (potentially each node needs to re-sign broadcast messages)
    - no easy way to overcome this problem
    - one approach is to avoid mutable information in control packets
    - another approach is to sacrifice some amount of security (e.g., SRP)
  - corrupted nodes can still add incorrect information and sign it
    - very tough problem …

Protection of untraceable modifications

- no perfect solution exists (trust problem)
- hop counts are often protected by a per-hop hashing mechanism (e.g., SAODV, SEAD)
  - control packets contain a hash value associated with the hop-count
  - when the control packet is forwarded or re-broadcast, the hop-count is incremented and the hash value is hashed once
  - adversarial nodes cannot decrease hop-count values in control packets because that would need to compute pre-images of hash values
  - adversary can still increase the hop-count …
- another approach is to eliminate hop-counts
  - use other routing metrics (e.g., ARAN uses the delay as the routing metric)

Combating gray holes

- two approaches:
  - use multiple, preferably disjoint routes
    - increased robustness
    - but also increased resource consumption
    - resource consumption can be somewhat decreased by applying the principles of error correcting coding
      - data packet is coded and the coded packet is split into smaller chunks
      - a threshold number of chunks is sufficient to reconstruct the entire packet
      - chunks are sent over different routes
  - detect and react
    - monitor neighbors and identify misbehaving nodes
    - use routes that avoid those misbehaving nodes
    - reputation reports about nodes can be spread in the network
    - this approach has several problems
      - how to detect reliably that a node is misbehaving?
      - how to prevent false accusations and spreading of negative reputations?

Some secure ad hoc network routing protocols

- SRP (on-demand source routing)
- Ariadne (on-demand source routing)
- endairA (on-demand source routing)
- S-AODV (on-demand distance vector routing)
- ARAN (on-demand, routing metric is the propagation delay)
- SEAD (proactive distance vector routing)
- SMT (multi-path routing combined error correcting)
- Watchdog and Pathrater (implementation of the “detect and react” approach to defend against gray holes)
- ODSBR (source routing with gray hole detection)

SRP (Secure Routing Protocol)

- SRP is a secure variant of DSR

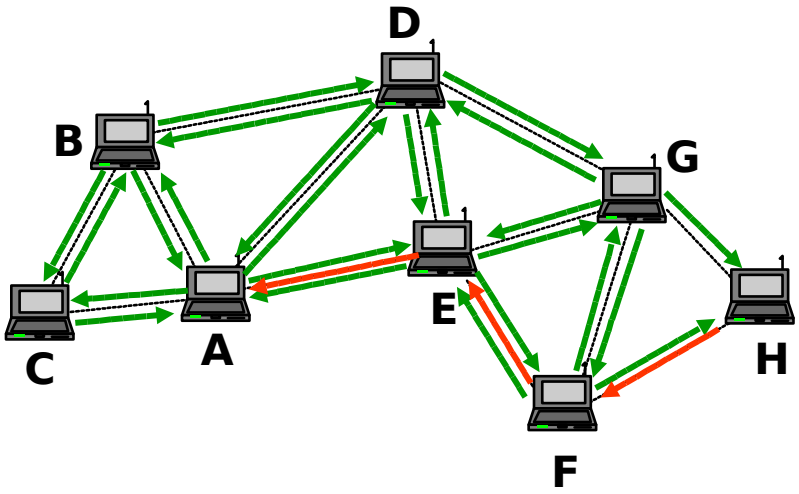
- uses symmetric-key authentication (MACs)
  - due to mobility, it would be impractical to require that the source and the destination share keys with all intermediate nodes
  - hence there's only a shared key between the source and the destination

  → only end-to-end authentication is possible

  → no optimizations

- SRP is simple but it does not prevent the manipulation of mutable information added by intermediate nodes
  - this opens the door for some attacks
  - some of those attacks can be thwarted by secure neighbor discovery protocols

SRP operation illustrated



A → * : [RREQ, A, H, id, sn, mac_{AH}, ()]

B → * : [RREQ, A, H, id, sn, mac_{AH}, (B)]

C → * : [RREQ, A, H, id, sn, mac_{AH}, (C)]

D → * : [RREQ, A, H, id, sn, mac_{AH}, (D)]

E → * : [RREQ, A, H, id, sn, mac_{AH}, (E)]

F → * : [RREQ, A, H, id, sn, mac_{AH}, (E, F)]

G → * : [RREQ, A, H, id, sn, mac_{AH}, (D, G)]

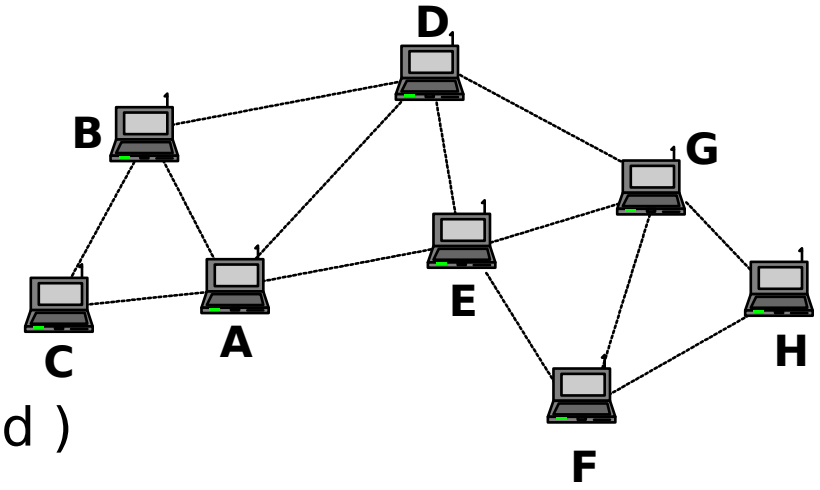
H → A : [RREP, A, H, id, sn, (E, F), mac_{HA}]

mac_{AH}: Message Authentication Code covering RREQ, A, H, id, and sn

Ariadne

- Ariadne is another secured variant of DSR
- it uses control message authentication to prevent modification and forgery of routing messages
  - based on signatures, MACs, or TESLA
- it uses a per-hop hash mechanism to prevent the manipulation of the accumulated route information in the route request message

Ariadne with signatures



A : $h_A = mac_{AH}(RREQ \mid A \mid H \mid id)$

A → * : [RREQ, A, H, id, h_A, (), ()]

E : $h_E = H(E \mid h_A)$

E → * : [RREQ, A, H, id, h_E, (E), (sig_E)]

F : $h_F = H(F \mid h_E)$

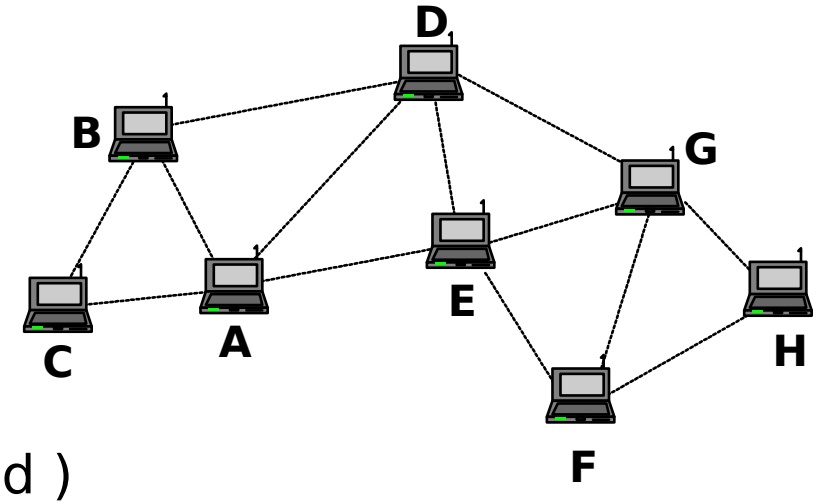
F → * : [RREQ, A, H, id, h_F, (E, F), (sig_E, sig_F)]

H → A: [RREP, H, A, (E, F), (sig_E, sig_F), sig_H] (sent via F and E)

Each signature is computed over the message fields preceding it

Ariadne with standard MACs

Assumption: each intermediate node shares a key with the destination.



A : $h_A = mac_{AH}(RREQ \mid A \mid H \mid id)$

A → * : [RREQ, A, H, id, h_A, (), ()]

E : $h_E = H(E \mid h_A)$

E → * : [RREQ, A, H, id, h_E, (E), (mac_{EH})]

F : $h_F = H(F \mid h_E)$

F → * : [RREQ, A, H, id, h_F, (E, F), (mac_{EH}, mac_{FH})]

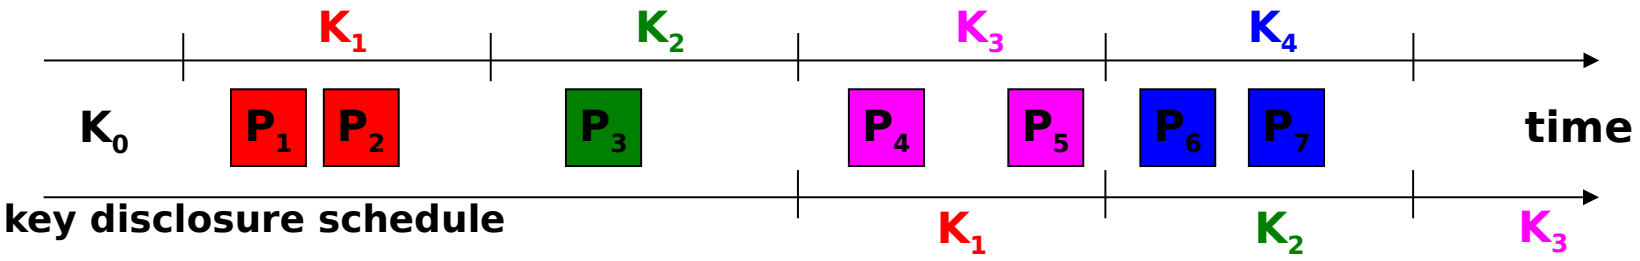
H → A : [RREP, H, A, (E, F), $mac_{...}$]

Symmetric-key broadcast authentication with TESLA

- MAC keys are consecutive elements in a one-way key chain:
  - $K_n \rightarrow K_{n-1} \rightarrow \ldots \rightarrow K_0$
  - $K_i = h(K_{i+1})$

- TESLA protocol:
  - setup: K_0 is sent to each node in an authentic way
  - time is divided into epochs
  - each message sent in epoch i is authenticated with key K_i
  - K_i is disclosed in epoch i+d, where d is a system parameter
  - K_i is verified by checking $h(K_i) = K_{i-1}$

- example:



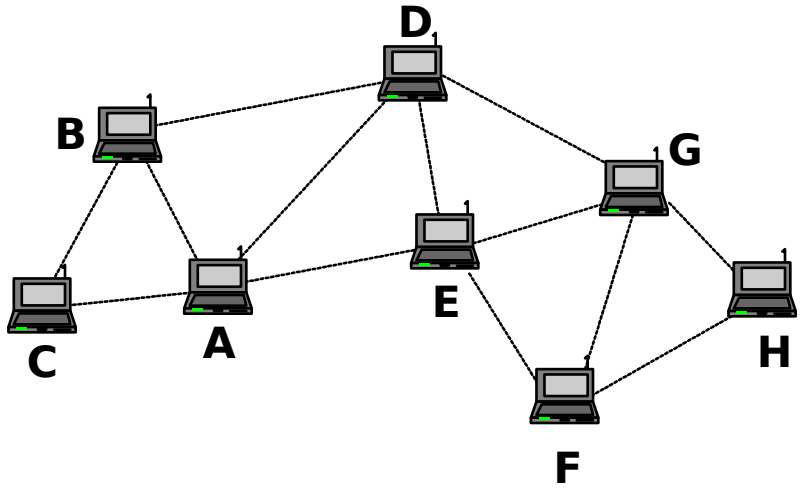
Ariadne with TESLA

- assumptions:
  - each source-destination pair (S, D) shares a symmetric key K_{SD}
  - each node F has a TESLA key chain $K_{F,i}$
  - each node knows an authentic TESLA key of every other node

- route request (source S, destination D):
  - S authenticates the request with a MAC using K_{SD}
  - each intermediate node F appends a MAC computed with its current TESLA key
  - D verifies the MAC of S
  - D verifies that the TESLA key used by F to generate its MAC has not been disclosed yet

- route reply:
  - D generates a MAC using K_{SD}
  - each intermediate node delays the reply until it can disclose its TESLA key that was used to generate its MAC
  - F appends its TESLA key to the reply
  - S verifies the MAC of D, and all the MACs of the intermediate nodes

Ariadne with TESLA illustrated



A → *: [RREQ, A, H, id, h_A, (), ()]

E → *: [RREQ, A, H, id, h_E, (E), ($mac_{K_{E,i}}$)]

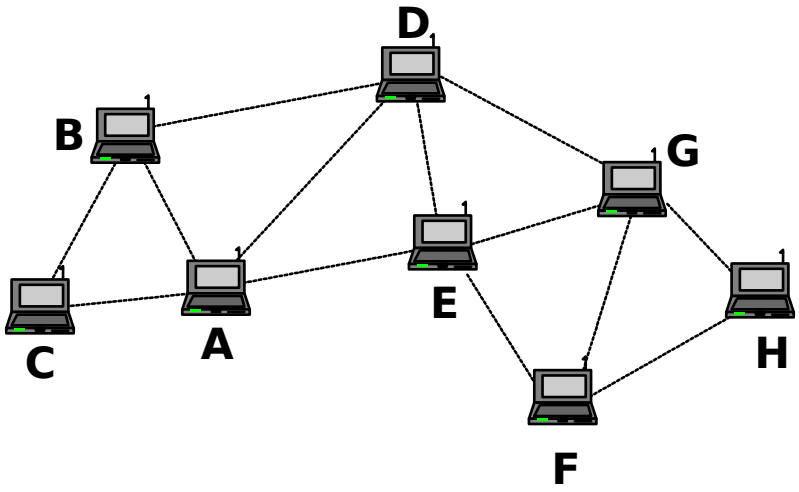
F → *: [RREQ, A, H, id, h_F, (E, F), ($mac_{K_{E,i}}$, $mac_{K_{F,i}}$)]

H → F: [RREP, H, A, (E, F), ($mac_{K_{E,i}}$, $mac_{K_{F,i}}$), mac_{HA}, ()]

F → E: [RREP, H, A, (E, F), ($mac_{K_{E,i}}$, $mac_{K_{F,i}}$), mac_{HA}, ($K_{F,i}$)]

E → A: [RREP, H, A, (E, F), ($mac_{K_{E,i}}$, $mac_{K_{F,i}}$), $mac_{K_{HA}}$, ($K_{F,i}$, $K_{E,i}$)]

endairA



target verifies:
- there's no repeating ID in the node list
- last node in the node list is a neighbor

each intermediate node verifies:
- its own ID is in the node list
- there's no repeating ID in the node list
- next and previous nodes in the node list are neighbors
- all signatures are valid

source verifies:
- there's no repeating ID in the node list
- first node in the node list is a neighbor
- all signatures are valid

A → * : [RREQ, A, H, id, ()]
E → * : [RREQ, A, H, id, (E)]
F → * : [RREQ, A, H, id, (E, F)]

H → F : [RREP, A, H, id, (E, F), (sig_H)]
F → E : [RREP, A, H, id, (E, F), (sig_H, sig_F)]
E → A : [RREP, A, H, id, (E, F), (sig_H, sig_F, sig_E)]

Properties of endairA

- security
  - endairA is provably secure if the signature scheme is secure against chosen message attacks

- efficiency
  - endairA requires less computation
    - route reply is signed and verified only by the nodes on the route
    - in Ariadne, route request is signed (and potentially verified) by every node in the network
